```

C preprocessor

- the C language is two languages
 - the language which defines data types, statements, functions and operators
 - there is also the language of the preprocessor (`#include`, `#define`) etc

- we use `#include` to include text within the current source file
 - traditionally these text files are `.h` files or library files, but they can be any text file, including `.c` files
 - however including `.c` files is generally considered bad practice
 - however there are exceptions to this rule, for example including machine generated `.c` files

Example #include

- the following is held in file `example.h`

```
int example_length (char *s);
```

Example #include

- the following is `main1.c`

```
#include <stdio.h>
#include "example.h"

main ()
{
    printf("my length program counts %d characters\n",
           example_length("hello world"));
}
```

example.c

```
int example_length (char *s)
{
    int i=0;

    while (s[i] != '\0')
        i++;

    return i;
}
```

#include

- notice that `main1.c` contained two `#includes`, the first was to include the prototype for `printf`
- also notice that it used `<>` to delimit the filename
 - special meaning, it searches using an implementation defined rule to find the file
- you can modify the search path of the `gcc` compiler by supplying the `-I` argument

#include

- you can compile and link these examples into an executable via:

```
$ gcc -g example.c main1.c
```

- and run the program via:

```
$ ./a.out
```

Macro substitution

- the C preprocessor allows text to be substituted, for example

```
#define forever while (1)
#include <stdio.h>

main ()
{
    forever {
        printf("hello world\n");
    }
}
```

Macro substituted with arguments

```
#define assert(X)    { if (!(X)) \
                    { fprintf(stderr, "assert failed\n"

main ()
{
    int r = write(1, "hello world\n", 12);
    assert(r==12);
}
```

- if you are unsure what is happening try asking the preprocessor what it is doing (use `gcc -E`)

Macro substituted with arguments

```
$ gcc -E main2.c
# 1 "main2.c"
# 1 "<built-in>"
# 1 "<command line>"
# 1 "main2.c"

main ()
{
    int r = write(1, "hello world\n", 12);
    { if (! (r==12)) { fprintf(stderr, "assert failed\n");
}
}
```

- use the C preprocessor carefully...
 - do not use the C preprocessor to gain execution speed (by avoiding a function call)
 - the C compiler will probably make better decisions than you..

Special tokens in the C preprocessor

- `__LINE__`, `__DATE__`, and `__FILE__` are all special tokens and are expanded into their obvious meanings, consider
- the gcc C compiler also substitutes `__FUNCTION__` (but it does this in the C language component - not during preprocessing)

Special tokens in the C preprocessor

```
#include <stdio.h>
#include <stdlib.h>
#define assert(X,Y) do_assert(X, Y, __LINE__, __FILE__, __

void do_assert (int b, char *m, int line, char *file,
                const char *func)
{
    if (! b) {
        fprintf(stderr, "%s:%d: %s in function %s (on %s)\n":
                file, line, m, func, __DATE__);
        exit(1);
    }
}

main ()
{
    int r = write(1, "hello world\n", 11); /* should be 12
    assert(r==12, "write failed");
}
```

gcc -E main3.c | tail -20

```
void do_assert (int b, char *m, int line, char *file,
                const char *func)
{
    if (! b) {
        fprintf(stderr, "%s:%d: %s in function %s (on %s)\n":
                file, line, m, func, "Feb 4 2008"
        )
        exit(1);
    }
}

main ()
{
    int r = write(1, "hello world\n", 11);
    do_assert(r==12, "write failed", 18, "main3.c", __FUNCT
}
```

Watch out for side effects

```
#define square(X) (X)*(X)

main ()
{
    int i=11;

    printf("square of %d is %d\n", i, square(i++));
    printf("square of %d is %d\n", i, square(i++));
}
```

- why is this wrong?
- never use C preprocessor for speed, unless you know the hardware better than the compiler author..

Correct solution

```
#include <stdio.h>

int square (int x)
{
    return x*x;
}

main ()
{
    int i=11;

    printf("square of 11 is %d\n", square(i++));
    printf("square of 12 is %d\n", square(i++));
}
```

- and compile with `gcc -O3 -g main4.c` it will produce great code

Compiler assembler output

- check this is the case!
- compile with `gcc -S -g -O3 main4.c`

main4.s

```
.LC0:
.string "square of 11 is %d0
.LC1:
.string "square of 12 is %d0
.text
main:
.loc 1 9 0
subq $8, %rsp
.loc 1 12 0
movl $121, %esi
movl $.LC0, %edi
xorl %eax, %eax
call printf
.loc 1 13 0
movl $144, %esi
movl $.LC1, %edi
xorl %eax, %eax
.loc 1 14 0
addq $8, %rsp
.loc 1 13 0
jmp printf
```

C preprocessor conditionals

- C preprocessor allows the following conditionals
 - `#if defined(MACRONAME)`
 - also abbreviated to `#ifdef MACRONAME`
 - first method is preferable as it can be used with conditional logic

C preprocessor conditionals

```

#define FOO
#define BAR "ok"

#if defined(FOO)
# include "myfunc1.h"
#elif defined(BAR) && (BAR == "ok")
# include "myfunc2.h"
#else
# include "myfunc3.h"
#endif

```

Revisiting the `example_length`

- goal is to create a prototype header file which allows external access to `example_length`
 - but also allow local prototype checking

`example2.h`

```

#if !defined(EXAMPLE_H)
# define EXAMPLE_H
# if defined(EXAMPLE_C)
#   define EXTERN
# else
#   define EXTERN extern
# endif

EXTERN int example_length (char *s);

#endif

```

example2.c

```

#define EXAMPLE_C
#include "example2.h"

int example_length (char *s)
{
    int i=0;

    while (s[i] != '\0')
        i++;
    return i;
}

```

main5.c

```

#include "example2.h"
#include <stdio.h>

main ()
{
    printf("my length program counts %d characters\n",
        example_length("hello world"));
}

```

Tutorial

- extend the example2 module above to include a function example_reverse whose prototype is:

```
char *example_reverse (char *s)
```

- and this function must be implemented to create a new string but copy the contents of, s, in reverse order

- hint you will need to use malloc

- extend main5.c to test your program

- finally read about the precedence operator ##

- finally what does the following code do?

- check the C preprocessor transformation

Tutorial

```

#include <stdio.h>
#define FOO(X)  #X " and this is something extra"
#define DEBUG(X) ("%s:%d:the value of " #X " is %d\n", \
    __FILE__, __LINE__, X)
#define BAR(X,Y) X ## Y

main()
{
    int i=9;
    int fred=3;

    printf(FOO(hi) " to do at the end of the " " lab\n");
    printf(DEBUG(i));
    printf("value of fred is %d\n", BAR(fr,ed));
}

```

Tutorial

- finally write a macro called `check_malloc` which has the same user prototype as `malloc` but checks that the result is non `NULL`
 - and calls `fprintf(stderr, etc, if the result is NULL`

- make it as useful as possible
